

Prevalence of Malnutrition in Mexican CAPD Diabetic and Nondiabetic Patients

Angeles Espinosa,¹ Alfonso M. Cueto-Manzano,¹ Consuelo Velazquez-Alva,² Ana Hernandez,¹ Nayeli Cruz,¹ Blanca Zamora,¹ Alejandra Chaparro,² Esther Irigoyen,² Ricardo Correa-Rotter¹

Malnutrition is often present on continuous ambulatory peritoneal dialysis (CAPD), and contributes to morbidity and mortality. Diabetic (DM)

levels are associated with an increasing prevalence of malnutrition, and this prevalence increases as the duration of dialysis increases. To identify the prevalence of malnutrition in CAPD patients with and without diabetes (NoDM), we identified 33 diabetic patients. These were subjected to a nutritional assessment which included a 37-hour dietary recall and a nutritional assessment protocol, including anthropometric, biochemical, and subjective evaluation, and food frequency patterns of personal and family members and 24 patients. In DM and 57 NoDM patients, moderate malnutrition was observed in 18% and 20% of malnutrition. DM was normal in 18% and 20% had mild, 29% had moderate, and 38% had severe malnutrition. Ninety-one percent of DM and 78% of NoDM showed some degree of malnutrition. DM patients had significantly higher levels of malnutrition ($p = 0.02$), were significantly older, had more body fat, and spent less time on dialysis. There were 37 males and 53 females. Sex distribution was similar between DM and NoDM. Seventy-six percent of males and 86% of females had malnutrition. Moderate and severe malnutrition were more frequent in females. DM and female sex were the strongest predictors for moderate and severe malnutrition.

Key words

Nutritional assessment, malnutrition, diabetes

Introduction

Protein calorie malnutrition (PCM) is a common finding in continuous ambulatory peritoneal dialysis (CAPD) patients (1,2) and has been associated with increased morbidity and mortality (3-5). Lower caloric intake has been identified to contribute to PCM in CAPD patients. Decreased intake, increased losses, and altered metabolism (2,6). Coexisting conditions such as uremia, infection, illness, psychosocial conditions, and depression may also contribute to the malnutrition observed in these patients. It is important in establishing a nutritional diagnosis in renal disease to use appropriate anthropometric measurements, biochemical measurements, and subjective global assessment (2,7). We better estimated malnutrition in CAPD patients (already diabetic (DM) CAPD patients PCM due to other chronic disease, vomiting) present at the time they began dialysis and probably due to the fact that their energy intake is often below the recommended. This condition could be due to their peritoneal losses than other patients (8). Our study aims to assess the nutritional status of our CAPD patients, to compare NE of DM and NoDM patients, as well as other clinical factors, and to identify risk factors for malnutrition.

Patients and methods
We selected 90 patients for clinical. Patients were cases two months of dialysis and within the last six weeks, performed using conventional, biochemical, and clinical

from a cohort at our CAPD. We looked if they had less than and a history of peritonitis. Nutritional assessment was performed using conventional anthropometric, biochemical, and subjective parameters.

TABLE I Patients' clinical and laboratory variables, according to the presence of diabetes mellitus (DM) and sex. Data are shown as mean ± SD

	Age (years)	Time on dialysis (months)	SCr (mg/dL)	BUN (mg/dL)	Hb (mg/dL)	Cholesterol (mg/dL)
DM	53±14	16±18	7.8±2.8	56±17	10.1±1.8	208±59
NoDM	39±16	34±32	11.1±4.6	61±22	8.8±2.2	200±50
p value	<0.001	0.004	<0.001	0.31	0.007	0.5
Male	47±15	31±31	11.6±5.0	64±19	9.7±2.3	186±40
Female	43±18	24±26	8.6±3.2	56±20	9.0±2.0	215±59
p value	0.31	0.29	<0.001	0.07	0.18	0.01

SCr = serum creatinine; BUN = blood urea nitrogen; Hb = hemoglobin; NoDM = nondiabetic.

Dietary intake were estimated by a 24-hour dietary recall. The estimate contained quantities without units accurately. The intake sources used were: fruits, glasses, ounces, and food portions of known quantities designed for this purpose (adapted from the National Survey of Diet and Health Habits, Precedent study).

energy intake (EI) and protein intake (PI) of the usual recommended daily allowances (RDA) (20 g/kg of body weight, and 1.2–1.3 g/kg protein/kg of body weight, respectively). We did not consider dialyzer glucose absorption.

Anthropometric measurements. Anthropometric measurements were obtained by trained personnel. Relative body weight (RBW) was calculated as the ratio of the patient's weight to the weight of a 70 kg individual. Midarm circumference (MAC) was measured at the mid-point between the olecranon and the acromion. Triceps skinfold thickness (TSF) was measured on the right arm, at the midpoint between the olecranon and the acromion. Midarm muscle area (MAMA) was measured at the mid-point between the olecranon and the acromion. Serum albumin (SA) was measured by a colorimetric method. Serum transferrin (ST) was measured by a radioimmunoassay method. Total lymphocyte count (TLC) was measured by a hemacytometer. Body mass index (BMI) was calculated as the ratio of the patient's weight to the square of the patient's height. Body fat (BF) was measured by a dual-energy X-ray absorptiometry (DXA) method.

TABLE II Nutritional Parameters, according to the presence of diabetes mellitus (DM) and sex. Data are shown as median (percentile: 25%–75%), as Student's t-test or Mann-Whitney U-test were respectively employed

EI (%)	PI (%)		RBW (%)	MAC (cm)	TSF (mm)	MAMA (cm ²)	SA (mg/dL)	ST (mg/dL)	TLC (cells/mm ³)	BMI	BF (%)

Results. Clinical and nutritional characteristics

We studied 90 patients with CAPD. The mean age was 68 years (range 45–85), 50% were male. The majority (80%) were on haemodialysis. The mean duration of dialysis was 3.5 years (range 0–15). The mean body mass index (BMI) was 26.5 kg m⁻² (range 18–35). The mean haemoglobin (Hb) was 12.5 g dl⁻¹ (range 10–15). The mean serum albumin was 3.5 g dl⁻¹ (range 2.5–4.5). The mean serum urea was 18 mg dl⁻¹ (range 10–25). The mean serum creatinine was 2.5 mg dl⁻¹ (range 1.5–4.5). The mean serum potassium was 4.5 mmol l⁻¹ (range 3.5–5.5). The mean serum calcium was 9.5 mg dl⁻¹ (range 8.5–10.5). The mean serum phosphate was 3.5 mg dl⁻¹ (range 2.5–4.5). The mean serum bicarbonate was 25 mmol l⁻¹ (range 20–30). The mean serum sodium was 135 mmol l⁻¹ (range 130–140). The mean serum chloride was 100 mmol l⁻¹ (range 95–105). The mean serum magnesium was 1.5 mmol l⁻¹ (range 1.0–2.0). The mean serum zinc was 100 µg dl⁻¹ (range 70–130). The mean serum copper was 1.0 mg dl⁻¹ (range 0.7–1.3). The mean serum selenium was 100 µg dl⁻¹ (range 70–130). The mean serum vitamin D was 20 ng ml⁻¹ (range 10–30). The mean serum vitamin E was 10 µg dl⁻¹ (range 7–13). The mean serum vitamin K was 1.0 µg dl⁻¹ (range 0.7–1.3). The mean serum vitamin B12 was 1000 pg ml⁻¹ (range 700–1300). The mean serum vitamin B6 was 100 ng ml⁻¹ (range 70–130). The mean serum vitamin C was 100 mg dl⁻¹ (range 70–130). The mean serum vitamin A was 100 µg dl⁻¹ (range 70–130). The mean serum vitamin D3 was 20 ng ml⁻¹ (range 10–30). The mean serum vitamin E was 10 µg dl⁻¹ (range 7–13). The mean serum vitamin K was 1.0 µg dl⁻¹ (range 0.7–1.3). The mean serum vitamin B12 was 1000 pg ml⁻¹ (range 700–1300). The mean serum vitamin B6 was 100 ng ml⁻¹ (range 70–130). The mean serum vitamin C was 100 mg dl⁻¹ (range 70–130). The mean serum vitamin A was 100 µg dl⁻¹ (range 70–130).

Statistical analysis

tion than NoDM ($p = 0.02$): 3 DM patients (9%) were normal, and 5 (14%) were mildly, 14 (40%) were moderately, and 13 (37%) were severely malnourished; whereas 13 NoDM (24%) patients were nor-

this could clearly explain this high frequency of malnutrition.

Our sample has a high proportion of DM patients, as this entity is the cause of end-stage renal disease

malnourished (Figure 1C). In order to investigate the role of albumin in the NS, we categorized the patients in two groups: one included patients with normal and moderate malnutrition, and a second one included patients who were moderately and severely malnourished. We observed a higher prevalence of DM in the higher levels of malnutrition. Such arrangement allowed us to establish a clear definite influence of DM and sex on NS (Figure 1 and 1D), and was further employed to analyze other malnutrition predictors. In the logistic regression analysis we found that the best model to select moderate and severe malnutrition included male sex and DM (Table III). We found collinearity between age and DM, yet we did not observe modifications in significance and odds ratio of female sex and DM when age was added to the model; however, when we excluded DM from the model, we did not gain in significance.

Discussion
Multiple studies have shown a high prevalence of albuminuria and hypoalbuminemia in CAPD patients, and some of them have demonstrated the influence of these variables over mortality and morbidity (2, 5, 17). Our study shows a strong influence

of DM in the prevalence of malnutrition in NoDM patients. We observed a higher prevalence of DM in the higher levels of malnutrition. Such arrangement allowed us to establish a clear definite influence of DM and sex on NS (Figure 1 and 1D), and was further employed to analyze other malnutrition predictors. In the logistic regression analysis we found that the best model to select moderate and severe malnutrition included male sex and DM (Table III). We found collinearity between age and DM, yet we did not observe modifications in significance and odds ratio of female sex and DM when age was added to the model; however, when we excluded DM from the model, we did not gain in significance.

We observed a higher frequency of moderate and severe malnutrition in DM and a similar trend in females (Figure 1A and 1C). In order to clarify the analysis, we classified our patients into two major groups: one included patients with normal NS and mild malnutrition, and the other included patients who were moderately and severely malnourished (Figure 1B and 1D). Using this arrangement we found a logistic regression model that predicts moderate and severe malnutrition, which includes female sex and DM, displaying similar predictive strength (odds ratio of 2.36 and 2.26, respectively) to our

We observed a higher frequency of moderate and severe malnutrition in DM and a similar trend in females (Figure 1A and 1C). In order to clarify the analysis, we classified our patients into two major groups: one included patients with normal NS and mild malnutrition, and the other included patients who were moderately and severely malnourished (Figure 1B and 1D). Using this arrangement we found a logistic regression model that predicts moderate and severe malnutrition, which includes female sex and DM, displaying similar predictive strength (odds ratio of 2.36 and 2.26, respectively) to our

ture, yet with a higher proportion of the moderately and severely malnourished. DM and female sex were the strongest predictive factors for moderate and severe malnutrition in this study.
